Because of their desirable characteristics multiple access networks are now used even in environments where a wired point-to-point network could have been installed. The understanding of the operation of multiple access network through their performance analysis is the focus of this book.

single sender on one end of the link, and a single receiver at the other end of the link. Many link-layer protocols have been designed for point-to-point links; PPP (the point-to-point protocol) and HDLC are two such protocols that we'll cover later in this chapter.

Frequency Division Multiple Access (FDMA) – The available bandwidth is divided into equal bands so that each station can be allocated its own band.

Guard bands are also added so that no to bands overlap to avoid crosstalk and noise.

Time Division Multiple Access (TDMA)

– In this, the bandwidth is shared between multiple stations. To avoid collision time is divided into slots and stations are allotted these slots to transmit data.

The lower sub-layer is responsible for multiple access resolution that is called media access control (MAC). The Sub-layer of the data link layer is shown in the figure below. The media access control protocol is divided into three protocols: The Random access, the Controlled-access, and the Channelization protocol.

Channelization is a multiple-access method in which the available bandwidth of a link is shared in time, frequency, or

through code, between different stations.

We discussed three channelization protocols: FDMA, TDMA, and CDMA.

In frequency-division multiple access (FDMA), the available bandwidth is divided into frequency bands. Each station is allocated a band to send its data.

Among the many factors that determine the performance of an access protocol include the propagation delay / packet transmission time ratio, the message arrival process, the types of feedback information available, the user population, and the ability of the user to sense the activities in the network.
